INSTRUCTIONS FOR USE

This protocol provides assistance in interpreting UnitedHealthcare benefit plans. When deciding coverage, the enrollee specific document must be referenced. The terms of an enrollee's document (e.g., Certificate of Coverage (COC) or Evidence of Coverage (EOC)) may differ greatly. In the event of a conflict, the enrollee's specific benefit document supersedes this protocol. All reviewers must first identify enrollee eligibility, any federal or state regulatory requirements and the plan benefit coverage prior to use of this Protocol. Other Protocols, Policies and Coverage Determination Guidelines may apply. UnitedHealthcare reserves the right, in its sole discretion, to modify its Protocols, Policies and Guidelines as necessary. This protocol is provided for informational purposes. It does not constitute medical advice. This policy does not govern Medicare Group Retiree members.

UnitedHealthcare may also use tools developed by third parties, such as the MCG™ Care Guidelines, to assist us in administering health benefits. The MCG™ Care Guidelines are intended to be used in connection with the independent professional medical judgment of a qualified health care provider and do not constitute the practice of medicine or medical advice.

COMMERCIAL COVERAGE RATIONALE

Manipulative therapy is **medically necessary** for treating musculoskeletal disorders, except as noted below.

Manipulative therapy is **not medically necessary** for treating:

- Non-musculoskeletal disorders (e.g., asthma, otitis media, infantile colic, etc.)
- Prevention/maintenance/custodial care
- Internal organ disorders (e.g., gallbladder, spleen, intestinal, kidney, or lung disorders)
- Temporomandibular Joint (TMJ) Disorder
- Scoliosis correction
Craniosacral therapy (cranial manipulation/Upledger technique) or manipulative services that utilize nonstandard techniques including but not limited to applied kinesiology, NUCCA, and neural organization technique are **not medically necessary** for any indication.

The role of manipulation for the above has not been established in scientific literature. A beneficial impact on health outcomes, e.g., improved physical function, durable pain relief, has not been established.

Manipulative therapy is **not medically necessary** when **ANY** of the following apply:

- The patient’s condition has returned to the pre-symptom state.
- Little or no improvement is demonstrated within 30 days of the initial visit despite modification of the treatment plan.
- Concurrent manipulative therapy, for the same or similar condition, provided by another health professional whether or not the healthcare professional is in the same professional discipline.

This protocol does not address manipulation under anesthesia; refer to the protocol titled “Manipulation under Anesthesia”, OTH032.

### MEDICARE COVERAGE RATIONALE

Medicare covers manipulative therapy when criteria are met. Refer to the National Coverage Determination (NCD) for Manipulation (150.1). Local Coverage Determinations (LCDs) for Nevada do exist; refer to the LCD for Chiropractic Services (L34242) (Accessed May 2017).

Medicare’s chiropractic coverage extends only to treatment by means of manual manipulation of the spine to correct a subluxation provided such treatment is legal in the State where performed. All other services furnished or ordered by chiropractors are **not covered**. For specific coverage requirements, refer to the Medicare Benefit Policy Manual Chapter 15 §30.5 and §240. Available at: [http://www.cms.gov/manuals/Downloads/bp102c15.pdf](http://www.cms.gov/manuals/Downloads/bp102c15.pdf).

### Manipulation (150.1)

**Indications and Limitations of Coverage**

A - Manipulation of the Rib Cage

Manual manipulation of the rib cage contributes to the treatment of respiratory conditions such as bronchitis, emphysema, and asthma as part of a regimen which includes other elements of therapy, and is **covered** only under such circumstances.

B - Manipulation of the Head

Manipulation of the occipitocervical or temporomandibular regions of the head when indicated for conditions affecting those portions of the head and neck is a **covered** service.

### Chiropractic Services (L34242)

**Coverage Indications, Limitations, and/or Medical Necessity**

Coverage of chiropractic service is specifically limited to treatment by means of manual manipulation, i.e., by use of the hands. Additionally, manual devices (i.e., those that are hand-held with the thrust of the force of the device being controlled manually) may be used by chiropractors in performing manual
Manipulative therapy involves the manipulation of the spine. However, no additional payment is available for use of the device, nor does Medicare recognize an extra charge for the device itself.

No other diagnostic or therapeutic service furnished by a chiropractor or under the chiropractor's order is covered. This means that if a chiropractor orders, takes, or interprets an x-ray, or any other diagnostic test, the x-ray or other diagnostic test, can be used for claims processing purposes, but Medicare coverage and payment are not available for those services. This prohibition does not affect the coverage of x-rays or other diagnostic tests furnished by other practitioners under the program. For example, an x-ray or any diagnostic test taken for the purpose of determining or demonstrating the existence of a subluxation of the spine is a diagnostic x-ray test covered if ordered, taken, and interpreted by a physician who is a doctor of medicine or osteopathy.

Effective for claims with dates of service on or after January 1, 2000, an x-ray is not required to demonstrate the subluxation. However, an x-ray may be used for this purpose if the chiropractor so chooses.

The word "correction" may be used in lieu of "treatment." Also, a number of different terms composed of the following words may be used to describe manual manipulation as defined above:

- Spine or spinal adjustment by manual means;
- Spine or spinal manipulation;
- Manual adjustment; and
- Vertebral manipulation or adjustment.

In any case in which the term(s) used to describe the service performed suggests that it may not have been treatment by means of manual manipulation, the carrier analyst refers the claim for professional review and interpretation.

Subluxation is defined as a motion segment, in which alignment, movement integrity, and/or physiological function of the spine are altered although contact between joint surfaces remains intact. A subluxation may be demonstrated by an x-ray or by physical examination, as described below.

1. Demonstrated by X-Ray
An x-ray may be used to document subluxation. The x-ray must have been taken at a time reasonably proximate to the initiation of a course of treatment. Unless more specific x-ray evidence is warranted, an x-ray is considered reasonably proximate if it was taken no more than 12 months prior to or 3 months following the initiation of a course of chiropractic treatment. In certain cases of chronic subluxation (e.g., scoliosis), an older x-ray may be accepted provided the beneficiary's health record indicates the condition has existed longer than 12 months and there is a reasonable basis for concluding that the condition is permanent. A previous CT scan and/or MRI is acceptable evidence if a subluxation of the spine is demonstrated.

2. Demonstrated by Physical Examination
Evaluation of musculoskeletal/nervous system to identify:
- Pain/tenderness evaluated in terms of location, quality, and intensity;
- Asymmetry/misalignment identified on a sectional or segmental level;
− Range of motion abnormality (changes in active, passive, and accessory joint movements resulting in an increase or a decrease of sectional or segmental mobility); and tissue, tone changes in the characteristics of contiguous, or associated soft tissues, including skin, fascia, muscle, and ligament.

To demonstrate a subluxation based on physical examination, two of the four criteria mentioned under "physical examination" are required, one of which must be asymmetry/misalignment or range of motion abnormality.

The history recorded in the patient record should include the following:
− Symptoms causing patient to seek treatment;
− Family history if relevant;
− Past health history (general health, prior illness, injuries, or hospitalizations; medications; surgical history);
− Mechanism of trauma;
− Quality and character of symptoms/problem;
− Onset, duration, intensity, frequency, location and radiation of symptoms;
− Aggravating or relieving factors; and
− Prior interventions, treatments, medications, secondary complaints.

Documentation Requirements: Initial Visit
The following documentation requirements apply whether the subluxation is demonstrated by x-ray or by physical examination:

1. History as stated above.
2. Description of the present illness including:
   − Mechanism of trauma;
   − Quality and character of symptoms/problem;
   − Onset, duration, intensity, frequency, location, and radiation of symptoms;
   − Aggravating or relieving factors;
   − Prior interventions, treatments, medications, secondary complaints; and
   − Symptoms causing patient to seek treatment.

These symptoms must bear a direct relationship to the level of subluxation. The symptoms should refer to the spine (spondyle or vertebral), muscle (myo), bone (osseo or osteo), rib (costo or costal) and joint (arthro) and be reported as pain (algia), inflammation (itis), or as signs such as swelling, spasticity, etc. Vertebral pinching of spinal nerves may cause headaches, arm, shoulder, and hand problems as well as leg and foot pains and numbness. Rib and rib/chest pains are also recognized symptoms, but in general other symptoms must relate to the spine as such. The subluxation must be causal, i.e., the symptoms must be related to the level of the subluxation that has been cited. A statement on a claim that there is "pain" is insufficient. The location of pain must be described and whether the particular vertebra listed is capable of producing pain in the area determined.

3. Evaluation of musculoskeletal/nervous system through physical examination.
4. Diagnosis: The primary diagnosis must be subluxation, including the level of subluxation, either so stated or identified by a term descriptive of subluxation. Such terms may refer either to the condition of the spinal joint involved or to the direction of position assumed by the particular bone named.

5. Treatment Plan: The treatment plan should include the following:
   − Recommended level of care (duration and frequency of visits);
   − Specific treatment goals; and
   − Objective measures to evaluate treatment effectiveness.

6. Date of the initial treatment.

**Documentation Requirements: Subsequent Visits**
The following documentation requirements apply whether the subluxation is demonstrated by x-ray or by physical examination:

1. History
   − Review of chief complaint;
   − Changes since last visit;
   − System review if relevant.

2. Physical exam
   − Exam of area of spine involved in diagnosis;
   − Assessment of change in patient condition since last visit;
   − Evaluation of treatment effectiveness.

3. Documentation of treatment given on day of visit.

The patient must have a significant health problem in the form of a neuromusculoskeletal condition necessitating treatment, and the manipulative services rendered must have a direct therapeutic relationship to the patient's condition and provide reasonable expectation of recovery or improvement of function. The patient must have a subluxation of the spine demonstrated by x-ray or physical exam as described above.

**Most spinal joint problems may be categorized as follows:**

1. **Acute subluxation:** A patient's condition is considered acute when the patient is being treated for a new injury, identified by x-ray or physical exam as specified above. The result of chiropractic manipulation is expected to be an improvement in, or arrest of progression of the patient's condition.

2. **Chronic subluxation:** A patient's condition is considered chronic when it is not expected to significantly improve or be resolved with further treatment (as in the case with an acute condition), but where the continued therapy can be expected to result in some functional improvement. Once the clinical status has remained stable for a given condition, without expectation of additional objective clinical improvements, further manipulative treatment is considered maintenance therapy and is **not covered**.

For Medicare purposes, a chiropractor **must** place an AT modifier on a claim when providing active/corrective treatment to treat acute or chronic subluxation. However the presence of the AT modifier may not in all instances indicate that the service is reasonable and necessary. As always, contractors may deny, if appropriate, after medical review.
3. **Maintenance therapy**: Maintenance therapy includes services that seek to prevent disease, promote health and prolong and enhance the quality of life, or maintain or prevent deterioration of a chronic condition. When further clinical improvement cannot reasonably be expected from continuous ongoing care, and the chiropractic treatment becomes supportive rather than corrective in nature, the treatment is then considered maintenance therapy. The AT modifier must not be placed on the claim when maintenance therapy has been provided. Claims without the AT modifier will be considered as maintenance therapy and denied. Chiropractors who give or receive from beneficiaries an ABN shall follow the instructions in Pub. 100-04, Medicare Claims Processing Manual, Chapter 23, section 20.9.1.1 and include a GA (or in rare instances a GZ) modifier on the claim. Maintenance therapy is **not a covered benefit**.

4. **Exacerbations**: An exacerbation is a temporary marked deterioration of the patient's condition due to flare-up of the condition being treated. This must be documented on the claim form and must be documented in the patient's clinical record, including the date of occurrence, nature of the onset or other pertinent factors that will support the reasonableness and necessity of treatments for this condition.

5. **Recurrence**: A recurrence is a return of symptoms of a previously treated condition that has been quiescent for 30 or more days. This may require the reinstitution of therapy.

6. **Contraindications**: Dynamic thrust is the therapeutic force or maneuver delivered by the physician during manipulation in the anatomic region of involvement.

   A relative contraindication is a condition that adds significant risk of injury to the patient from dynamic thrust, but does not rule out the use of dynamic thrust. The doctor should discuss this risk with the patient and record this in the chart.

   The following are relative contraindications to dynamic thrust:
   - Articular hypermobility and circumstances where the stability of the joint is uncertain;
   - Severe demineralization of bone;
   - Benign bone tumors (spine);
   - Bleeding disorders and anticoagulant therapy; and
   - Radiculopathy with progressive neurological signs.

   Dynamic thrust is **absolutely contraindicated** near the site of demonstrated subluxation and proposed manipulation in the following:
   - Acute arthropathies characterized by acute inflammation and ligamentous laxity and anatomic subluxation or dislocation; including acute rheumatoid arthritis and ankylosing spondylitis;
   - Acute fractures and dislocations or healed fractures and dislocations with signs of instability;
   - An unstable odontoid process;
   - Malignancies that involve the vertebral column;
   - Infection of bones or joints of the vertebral column;
   - Signs and symptoms of myelopathy or cauda equina syndrome;
   - For cervical spinal manipulations, vertebrobasilar insufficiency syndrome; and
   - A significant major artery aneurysm near the proposed manipulation.
Location of Subluxation:
The precise level of the subluxation must be specified by the chiropractor to substantiate a claim for manipulation of the spine. This designation is made in relation to the part of the spine in which the subluxation is identified:

Area of Spine - Names of Vertebrae - Number of Vertebrae - Short Form or Other Name
Neck - Occiput (Occ, CO), Cervical (C1 thru C7), Atlas (C1), Axis (C2) - 7
Back - Dorsal (D1 thru D12) or Thoracic (T1 thru T12) or Costovertebral (R1 thru R12) or Costotransverse (R1 thru R12) - 12
Low Back - Lumbar (L1 thru L5) - 5
Pelvis - Iii, r and l (I, Si)
Sacral - Sacrum, Coccyx, S, SC

In addition to the vertebrae and pelvic bones listed, the Iii (R and L) are included with the sacrum as an area where a condition may occur which would be appropriate for chiropractic manipulative treatment.

There are two ways in which the level of the subluxation may be specified:
− The exact bones may be listed, for example: C5, C6, etc.
− The area may suffice if it implies only certain bones such as: Occipito-atlantal (occiput and C1 (atlas)), lumbo-sacral (L5 and Sacrum), sacro-iliac (sacrum and ilium).

Following are some common examples of acceptable descriptive terms for the nature of the abnormalities:
− Off-centered
− Misalignment
− Malpositioning
− Spacing - abnormal, altered, decreased, increased
− Incomplete dislocation
− Rotation
− Listhesis - antero, postero, retro, lateral, spondylo
− Motion - limited, lost, restricted, flexion, extension, hypermobility, hypomotility, aberrant

Other terms may be used. If they are understood clearly to refer to bone or joint space or position (or motion) changes of vertebral elements, they are acceptable

Treatment Parameters
The chiropractor should be afforded the opportunity to effect improvement or arrest or retard deterioration in such condition within a reasonable and generally predictable period of time. Acute subluxation (e.g., strains or sprains) problems may require as many as three months of treatment but some require very little treatment. In the first several days, treatment may be quite frequent but decreasing in frequency with time or as improvement is obtained.

Chronic spinal joint condition implies, of course, the condition has existed for a longer period of time and that, in all probability, the involved joints have already "set" and fibrotic tissue has developed. This condition may require a longer treatment time, but not with higher frequency.
Some chiropractors have been identified as using an "intensive care" concept of treatment. Under this approach multiple daily visits (as many as four or five in a single day) are given in the office or clinic and so-called room or ward fees are charged since the patient is confined to bed usually for the day. The room or ward fees are not covered and reimbursement under Medicare will be limited to not more than one treatment per day.

For Medicare and Medicaid Determinations Related to States Outside of Nevada:
Please review Local Coverage Determinations that apply to other states outside of Nevada.
http://www.cms.hhs.gov/mcd/search

Important Note: Please also review local carrier Web sites in addition to the Medicare Coverage database on the Centers for Medicare and Medicaid Services’ Website.

MEDICAID COVERAGE RATIONALE

603.6 CHIROPRACTIC SERVICES POLICY (accessed May 2017)

Medicaid will pay for a chiropractic manual manipulation of the spine to correct a subluxation if the subluxation has resulted in a neuro-musculoskeletal condition for which manipulation is the appropriate treatment. Services are limited to Medicaid eligible children under the age of 21 and Qualified Medicare Beneficiaries (QMB’s).

A. Prior authorization is not required for:
   1. Four or less chiropractic office visits (emergent or non-emergent) for children under 21 years of age in a rolling 365 days. The visits must be as a direct result of an EPSDT screening examination, diagnosing acute spinal subluxation.
   2. Chiropractic services provided to a QMB recipient.

B. Prior authorization is required for:
   1. Chiropractic visits for children under 21 years of age whose treatment exceeds the four visits. The physician must contact the Nevada Medicaid QIO-like vendor for prior authorization.

U.S. FOOD AND DRUG ADMINISTRATION (FDA)

A manipulative service is a procedure and therefore not subject to FDA regulation.

Craniosacral therapy is a type of osteopathic treatment and therefore not subject to FDA Regulation.

DESCRIPTION OF SERVICES

Manipulative treatment, also known as mobilization therapy or “adjustment,” refers to manual therapy employed to soft or osseous tissues for therapeutic purposes. This term encompasses a wide variety of physical manipulations, including rhythmic stretching, deep pressure and traction, and spinal adjustments. Spinal manipulation involves manual and mechanical interventions that may be high or low velocity; short or long lever; high or low amplitude; with or without recoil. Most often, manipulation is performed by applying a controlled force into a joint or joints of the spinal column to
reduce or correct a specific derangement. Depending on the provider specialty, a joint derangement may be listed as a subluxation, vertebral subluxation complex, osteopathic lesion, somatic dysfunction or a mechanical dysfunction.

Craniosacral therapy (CST) is a noninvasive osteopathic technique that involves the therapist touching the patient to detect pulsations and rhythms of flow of cerebrospinal fluid (CSF). The therapist then gently works with the skull and spine, with the goal to effect release of potential restrictions to the flow of CSF, without the use of forceful physical manipulation (Hayes, 2016). It is considered a treatment for a variety of conditions, such as multiple sclerosis, asthma, pelvic pain, fibromyalgia, and tension-type and migraine headaches. Many of these disease states are associated with acute and chronic pain. A variety of non-standard manipulative therapy techniques exist such as applied kinesiology, National Upper Cervical Chiropractic Association (NUCCA), and neural organizational technique.

Applied kinesiology, also known as muscle strength testing, is a method of diagnosis and treatment based on the belief that various muscles are linked to particular organs and glands, and that specific muscle weakness can signal distant internal problems such as nerve damage, reduced blood supply, chemical imbalances or other organ or gland problems. Practitioners contend that by correcting this muscle weakness, you can help heal a problem in the associated internal organ.

The NUCCA technique is a variation of chiropractic care with the goal to improve structural and sustained postural balance that leads to improved spinal stability along with balanced mobility.

The neural organizational technique attempts to treat the cause, the whole person, and work with what the body communicates is out of balance.

Manipulative treatment may be a primary method of treatment for some medical conditions, and for others it may complement or support medical treatment. (Axen, et.al., 2009) Individuals may elect to receive care that may mitigate the development of a disorder i.e., primary prevention. Clinicians may provide manipulative therapy in an attempt to prevent new events (secondary prevention) or maintain patients at their best possible level once improvement has been achieved (tertiary prevention).

**CLINICAL EVIDENCE**

Manipulative therapy may be employed as a treatment for many conditions of the spine, such as low-back pain and cervical and thoracic spine disorders. Manipulative therapy may be used as treatment for extremity joint and temporomandibular joint (TMJ) conditions. The long-term safety and effectiveness of the use of chiropractic management and manual therapies in the treatment of non-neuromusculoskeletal conditions, including but not limited to hypertension, obesity, rheumatoid arthritis, smoking, asthma, colic and otitis media have not been proven in the medical literature through long-term, randomized, controlled clinical trials.

**Musculoskeletal Disorders**

A randomized controlled trial by Puntumetakul et al. (2015) studied forty-eight patients with chronic mechanical neck pain (CMNP). The patients were randomly allocated to single-level thoracic manipulation (STM) at T6-T7 or multiple-level thoracic manipulation (MTM), or to a control group (prone lying). Cervical range of motion (CROM), visual analog scale (VAS), and the Thai version of
the Neck Disability Index (NDI-TH) scores were measured at baseline, and at 24-hour and 1-week follow-up. At 24-hour and 1-week follow-up, neck disability and pain levels were significantly (P<0.05) improved in the STM and MTM groups compared with the control group. CROM in flexion and left lateral flexion were increased significantly in the STM group when compared with the control group at 1-week follow-up. The CROM in right rotation was increased significantly after MTM compared to the control group at 24-hour follow-up. There were no statistically significant differences in neck disability, pain level at rest, and CROM between the STM and MTM groups. The authors concluded that the results suggest that both single-level and multiple-level thoracic manipulation improve neck disability, pain levels, and CROM at 24-hour and 1-week follow-up in patients with CMNP.

Schwerla et al. (2015) conducted a randomized controlled trial on the use of OMT in women with persistent postpartum lower back pain (LBP) greater than 3 months. Women were allocated to an OMT group (n=40) and a waitlist control group (n=40) for a period of 8 weeks. OMT was provided 4 times at intervals of 2 weeks, with a follow-up after 12 weeks. The control group was not allowed any additional pain relief, e.g., medication, physical therapy, during this time. The main outcome measures were pain intensity as measured by a visual analog scale and the effect of LBP on daily activities as assessed by the Oswestry Disability Index (ODI). Based on the results of 8 weeks of therapy, the authors reported that this study provides some evidence that patients with pregnancy- and childbirth-related LBP may be successfully treated with OMT. Further studies that include prolonged follow-up periods are warranted to corroborate the current findings.

A 2014 cohort study by Leeman et al. evaluated 148 patients between the ages of 18 and 65 with low back and leg pain due to MRI confirmed herniated disc, who were being treated with high velocity and low amplitude spinal manipulation in terms of their short-, medium-, and long-term outcomes of self-reported global impression of change and pain levels at various time points up to 1 year and to determine if outcomes differ between acute and chronic patients using a prospective, cohort design. The type of manipulation was dependent upon whether the disc herniation was intraforaminal or paramedian as seen on the magnetic resonance images and was performed by a doctor of chiropractic. Outcomes included the patient's global impression of change scale for overall improvement, the NRS for LBP, leg pain, and the Oswestry questionnaire at 2 weeks, 1, 3, and 6 months, and 1 year after the first treatment. The proportion of patients reporting "improvement" on the patient's global impression of change scale was calculated for all patients and acute vs. chronic patients. At the conclusion of the study a large percentage of acute and importantly chronic lumbar disc herniation patients treated with chiropractic spinal manipulation reported clinically relevant improvement.

In a systematic review of the comparative effectiveness of osteopathic manipulation (OMT), Steel et al. (2017) found that despite some positive findings, published comparative effectiveness and health economic studies in OMT are of insufficient quality and quantity to inform policy and practice. High quality, well-designed research that aligns with clinical best practice is greatly needed to build a pragmatic evidence base for OMT.

In a systematic review and meta-analysis of 15 trials with 18 comparison groups and 1502 participants, Franke et al. (2014) assessed OMT for the treatment of non-specific low back pain. The authors concluded that clinically relevant effects of OMT were found for reducing pain and improving functional status in patients with acute and chronic nonspecific LBP (moderate quality evidence) and
for LBP in pregnant (low quality evidence) and postpartum women at 3 months post-treatment (moderate quality evidence). Given the small sample sizes, different comparison groups in different studies, heterogeneity, and lack of long-term measurement, larger, high-quality RCTs with robust comparison groups are needed to provide firm conclusions regarding the effectiveness of OMT for LBP.

A 2011 Cochrane review by Rubinstein et al. (2011) evaluated 26 randomized controlled trials that assessed the effects of spinal manipulative therapy (SMT) in 6070 patients with chronic low-back pain. They concluded that SMT appears to be as effective as other common therapies prescribed for chronic low-back pain, such as, exercise therapy, standard medical care or physiotherapy. However, it is less clear how it compares to no treatment or sham (placebo) treatment.

In a 2010 Cochrane review by Walker et al., 12 studies involving 2887 participants were evaluated to assess the various combinations of chiropractic care for low-back pain. The review showed that while combined chiropractic interventions slightly improved pain and disability in the short term and pain in the medium term for acute and subacute low-back pain, there is currently no evidence to support or refute that combined chiropractic interventions provide a clinically meaningful advantage over other treatments for pain or disability in people with low-back pain.

An updated 2015 Cochrane review of manipulation or mobilization for neck pain included 51 trials involving 2920 participants. The authors concluded that manipulation and mobilization present similar results for every outcome at immediate/short/intermediate-term follow-up. Multiple cervical manipulation sessions may provide better pain relief and functional improvement than certain medications at immediate/intermediate/long-term follow-up. Since the risk of rare but serious adverse events for manipulation exists, further high quality research focusing on mobilization and comparing mobilization or manipulation versus other treatment options is needed to guide clinicians in their optimal treatment choices (Gross, 2015).

A meta-analysis by Chou et al. (2007) evaluated non-pharmacologic therapies for acute and chronic low back pain and found that there is good evidence spinal manipulation is moderately effective for subacute and chronic low back pain; and fair evidence for small to moderate benefits for acute low back pain.

A comparative effectiveness report was published under the auspices of the Agency for Healthcare Research and Quality (AHRQ), which updated of the 2007 meta-analysis. (Chou, et al; 2016) The authors qualitatively examined whether the results of new studies were consistent with pooled or qualitative findings from prior systematic reviews. For acute low back pain, there was limited evidence that spinal manipulation is associated with some beneficial effects versus a sham therapy, no intervention, or usual care. The beneficial effects of manipulative therapy were small to moderate in magnitude for the treatment of chronic low back pain. The assessment and reporting of harms for non-pharmacological therapies including spinal manipulation were suboptimal but indicated no serious harms. Reported harms were generally related to superficial symptoms at the application site or a temporary increase in pain.

Dagenais et al. (2010) conducted a systematic review to evaluate spinal manipulation therapy for low back pain. Of 699 studies, 14 (n = 2,027 patients) were included for review. Spinal manipulation...
therapy was most commonly compared to physical modalities, education, medication, exercise, mobilization, or sham therapy. The authors found that the results from most studies suggest that 5 to 10 sessions of spinal manipulation therapy administered over 2 to 4 weeks achieve equivalent or superior improvement in pain and function when compared with other commonly used interventions for short, intermediate, and long-term follow-up.

A systematic review by Licciardone et al. (2005) of 6 osteopathic manipulative treatment (OMT) clinical trials were evaluated to assess the efficacy of OMT as a complementary treatment for low back pain. A total of 525 subjects with low back pain were randomized in the eligible trials. Overall, OMT significantly reduced low back pain (effect size, -0.30; 95% confidence interval, -0.47 - -0.13; P = .001). Stratified analyses demonstrated significant pain reductions in trials of OMT vs. active treatment or placebo control and OMT vs. no treatment control. The authors concluded that OMT significantly reduces low back pain and the level of pain reduction was greater than expected from placebo effects alone. This review was limited by the various study designs such as the methodology, trial setting, subject characteristics, OMT and control treatment interventions, and pain measures.

Comprehensive evidence syntheses of the effectiveness of manual therapies including manipulation were published by Bronfort et al. (2010) and updated by Clar et al. (2014). Both reported that spinal manipulation is effective for the treatment of acute low back pain, acute/subacute neck pain, and chronic neck pain (when combined with exercise). Neither report found conclusive evidence for cervical manipulation/mobilization for tension type headaches as well as manipulation alone for coccydynia, sciatica and fibromyalgia. In contrast to the earlier report by Bronfort, et al. (2010), the evidence synthesis by Clar, et al (2014) concluded there is moderate (positive) evidence for mobilization techniques for the treatment of cervicogenic headache.

Vernon et al (2009) report that only 2 clinical trials of spinal manipulation for adult tension type headache have been reported, neither of which was fully controlled.

Leaver et al. (2010) conducted a randomized controlled trial comparing manipulation with mobilization for recent onset of neck pain in 182 patients. Patients were randomly assigned to receive 4 treatments of either neck manipulation (n=91) or mobilization (n=91) over 2 weeks. Outcomes were measured by the number of days taken to recover from the episode of neck pain. Median days to recovery were 47 for the manipulation group and 43 days for the mobilization group. The authors concluded that manipulation was no more effective than mobilization in treating recent onset of neck pain.

A prospective, multicenter study by Rubinstein et al. (2007), evaluated 529 patients with neck pain to assess clinical outcomes and adverse events. Follow-up occurred at 3 and 12 months using questionnaires. Fifty-six percent of patients reported worsening of symptoms or onset of a new symptom during any one of the first 3 treatments. Only 5 patients (1%) reported to be much worse at 12 months. No serious adverse events were recorded during the study period. The authors concluded that while adverse events may be common, they are rarely severe in intensity. Most patients report recovery, particularly in the long term. Therefore, the benefits of chiropractic manipulative therapy for neck pain seem to outweigh the potential risks.
Non-musculoskeletal disorders (e.g., asthma, otitis media, infantile colic, etc)
Numerous systematic literature reviews have investigated manipulative therapies for a range of non-musculoskeletal disorders. There were five relevant systematic reviews address the treatment of respiratory disorders such as asthma (Alcantara, et.al, 2012; Hondras, et.al, 2005; Kaminskyj, et.al, 2010; Pepino, et.al., 2013) cystic fibrosis, bronchiolitis, recurrent infections (Pepino, 2013); pneumonia (Yang, et.al., 2013); and chronic pulmonary obstructive disease (Heneghan, et.al.,2013). Four systematic reviews examined the use of manipulation for the management of gastrointestinal disorders affecting infants e.g., infantile colic (Alcantara,et.al., 2011; Dobson,et.al., 2012), adults for irritable bowel syndrome (Müller,et.al., 2013), gastroesophageal reflux and duodenal ulcers (Ernst, 2011).

Three systematic reviews reported on the efficacy of manual therapy for the treatment of otitis media. (Carr and Nahata, 2006; Leighton, 2009; Pohlman, 2012).

Single systematic reviews of manipulation as part of manual therapy interventions were identified for the treatment of attention deficit hyperactivity disorder [ADHD] (Karpouzis,et.al, 2010), hypertension (Mangum,et.al., 2012), nocturnal enuresis (Huang,et.al., 2011), insomnia (Kingston, et.al,2010), and lower urinary tract symptoms [LUTS] (Franke and Hoesele, 2013).

Collectively, the direction of outcomes favored subjects receiving manual therapy interventions. However, the limited number of studies and the quality of research evidence (designs, methodologies, sample sizes, variation of interventions, and outcomes measured) do not permit confident judgments about the effectiveness and safety of manual therapy interventions including manipulation for the treatment of non-musculoskeletal disorders.

Additional systematic reviews that included a range of non-musculoskeletal disorders found the evidence lacking, inconclusive, or unproven in assessing the effectiveness of manual therapy interventions including manipulative therapy for the treatment of non-musculoskeletal disorders . (Clar et al., 2014; Posadzki et al., 2013; Gleberzon et al.,2012; Gotlib and Rupert, 2008; Ferrance and Miller, 2010; Cole and Reed, 2010).

Prevention Manipulative Treatment Care
Martel et al. (2011) conducted a randomized controlled trial to compare the efficacy of preventive spinal manipulative therapy (SMT) to no treatment in 108 patients with non-specific chronic neck pain. The trial was divided into 2 phases. The first was the non-randomized, symptomatic phase during which all eligible participants received a short course of SMT. Ten patients dropped out of the study following the symptomatic phase. After completing the symptomatic phase, the remaining 98 participants were randomly assigned to 1 of 3 parallel groups (no treatment (n =29), a SMT group (n = 36) or a SMT plus exercise group (n = 33)). The second preventive phase lasted 10 months. Outcomes were measured using visual analog scale (VAS), active cervical ranges of motion (cROM), the neck disability index (NDI) and the Bournemouth questionnaire (BQ). Patients were also asked to keep an exercise diary. Mean adherence to the home exercise program was 48.8%. In the preventive phase, all 3 groups showed outcomes scores similar to those obtain following the non-randomized, symptomatic phase. Overall spinal manipulation or spinal manipulation combined with exercises did not have any significant advantages when compared to the no treatment strategy. The authors found that preventive therapy was no more effective than no treatment at all for patients with non-specific chronic neck pain.
A randomized controlled trial by Senna and Machaly (2011) investigated the effects of maintenance spinal manipulation therapy for chronic non-specific low back pain. Subjects were randomized into 3 groups and followed for 10 months. Group 1 (n=40) received sham manipulation during the first month and no treatment over the subsequent 9 months. Group 2 (n=27) received manipulation during the first month but no treatment during the following 9 months. Group 3 (n=26) received manipulation during the first month and ‘maintenance’ manipulation every 2 weeks for an additional 9 months. At the end of 10 months, 33 subjects declined follow-up. Five withdrew in the first phase before treatment began. Of the remaining 88 subjects, 80 were evaluated at 4 months, 71 at 7 months and 60 at 10 months. Subjects in groups 2 and 3 experienced significantly lower pain and disability scores compared to the control group after the initial 1-month treatment period. At the end of 10 months, group 3 reported significantly lower pain and disability scores compared to Group 2. The authors concluded that spinal manipulation is an effective treatment for chronic non-specific low back pain. While Group 3 reported better outcomes, the basis of this improvement could not be determined as to whether it was the manipulation or the placebo effect of continued visits. The study is further limited by serious methodological flaws e.g., 35% drop-out rate; incomplete outcome data; lack of blinding; and uncertainty about allocation concealment, use of co-interventions, and compliance across groups.

Brumm et al. (2012) conducted a prospective cohort study to apply a preventive OMT protocol for cross-country athletes to reduce the incidence of stress fractures. Examinations of cross-country athletes at an NCAA (National Collegiate Athletic Association) Division I university were performed over successive academic years. More than 1800 participant examinations were performed on 124 male and female participants over the course of 5 consecutive academic years. Data from these academic years were compared with data from the previous 8 academic years. The intervention included osteopathic structural examination and OMT that focused on somatic dysfunction identified in the pelvis, sacrum, and lower extremities. According to the authors, the results demonstrated a statistically significant decrease in the cumulative annual incidence of stress fractures in male, but not female, cross-country athletes after receiving OMT. Further research with randomized controlled trials is needed to validate these findings.

**Internal organ disorders**

A 2015 Hayes search and summary report examined the use of noninvasive visceral manipulation for visceral organ dysfunction. There is a small body of literature published in the last 10 years examining the use of noninvasive visceral manipulation for visceral organ dysfunction. A total of 8 abstracts were retrieved, including 1 randomized crossover placebo-controlled study, 1 prospective randomized controlled trial, 1 prospective pilot study, 2 case reports, 2 systemic reviews, and 1 review article. There is insufficient published evidence to assess the safety and/or impact on health outcomes or patient management for the use of noninvasive visceral manipulation for visceral organ dysfunction. It should be noted that this report focused on visceral manipulation in general. The retrieved abstracts focused on the use of visceral manipulation for various indications, including deep infiltrating endometriosis with colorectal involvement, meconium excretion in premature infants, irritable bowel syndrome, biliary dyskinesia, COPD, and functional dyspepsia. These studies all had significant limitations, including lack of blinding, small sample size, use of largely qualitative or subjective outcome measures.
Temporomandibular Joint (TMJ) Disorders

In a prospective case series, Grondin and Hall (2017) investigated the influence of OMT on pain and range of motion (ROM) of the TMJ and cervical spine including flexion-rotation test (FRT) in patients (n=12) suffering chronic pain arising from chronic arthralgic temporomandibular disorder (TMD). A paired t-test revealed significant improvement following the intervention in disability (p < 0.001), VAS pain score at rest (p < 0.001) and at maximum mouth opening (p < 0.001), jaw opening ROM (p < 0.001), FRT ROM to the left (p = 0.024) and right (p = 0.001). In contrast, no significant change was identified for total cervical ROM (p = 0.905). After the intervention, five patients (41.66%) had no pain at rest or at maximal mouth opening, and all had a negative FRT. The authors reported that the effect sizes indicate a moderate to strong, clinically significant effect for all variables apart from total cervical ROM. While a case series cannot identify a cause and effect relationship, the authors concluded that the results provide preliminary evidence for the influence of TMJ manual therapy on measures of TMD including pain, as well as upper but not whole cervical movement and associated pain in patients with a diagnosis of TMJ arthralgia. Small sample size, no control group, and short-term follow-up were limitations to this study.

Cuccia et al. (2010) conducted a randomized controlled trial to test the hypothesis that OMT might be effective in alleviating symptoms of TMD. Patients were randomly divided into two groups: an OMT group (25 patients) and a conventional conservative therapy (CCT) group (25 patients). At the first visit (T0), at the end of treatment (after six months, T1) and two months after the end of treatment (T2), all patients were subjected to clinical evaluation. Assessments were performed by subjective pain intensity (visual analogue pain scale, VAS), clinical evaluation (Temporomandibular index) and measurements of the range of maximal mouth opening and lateral movement of the head around its axis. The authors reported that patients in both groups improved during the six months, and the OMT group required significantly less medication (non-steroidal medication and muscle relaxants). Based on their findings, the authors concluded that OMT is a valid option in the treatment of TMD. Lack of longer-term outcomes was a limitation to this study.

de Felicio et al. (2010) conducted a randomized controlled trial to analyze the effects of OMT on the treatment of patients with associated articular and muscular temporomandibular disorder (TMD) symptoms. Patients (n=30) were randomly divided into groups: 10 were treated with OMT (T group), 10 with an occlusal splint (OS group), and 10 untreated control group with TMD (SC). During the final phase of treatment, groups T and OS presented significant improvement, however, the group T presented better results and differed significantly from group OS in muscular pain, TMJ pain, and the number and length of headaches. Limitations of this study include small sample size, nondescript length of treatment, and short follow-up period.

Armijo-Olivo et al. (2016) conducted a systematic review and meta-analysis to determine the methodological quality of randomized controlled trials that examined the effectiveness of manual therapy and therapeutic exercise interventions compared with other active interventions or standard care for treatment of TMD. The overall evidence for this systematic review was considered by the authors to be low. The trials included in this review had unclear or high risk of bias. Thus, the evidence was generally downgraded based on assessments of risk of bias. Most of the effect sizes were low to moderate, with no clear indication of superiority of exercises versus other conservative treatments for TMD. However, manual therapy alone or in combination with exercises at the jaw or cervical level showed promising effects.
Morel (2016) conducted a literature review to determine whether manual therapy improved signs and symptoms of temporomandibular disorders. He concluded that there is widely varying evidence that manual therapy improves pain, maximum mouth opening and pressure pain threshold in subjects with TMD signs and symptoms, depending on the technique. Further studies are needed with standardized evaluations and better study designs to strengthen clinical relevance.

A comprehensive review by Bronfort et al. (2010) found that the evidence for treating TMJ disorders with manipulation is inconclusive. The results of an updated review on the comparative effectiveness/safety of manual therapy including osteopathic manipulation for temporomandibular disorders remained inconclusive. (Clar, 2014).

Two reviews by McNeely et al. (2006) and Medlicott and Harris (2006) concluded there is limited evidence for the use of manual therapy in the treatment of temporomandibular joint dysfunction.

There is insufficient long-term evidence that manipulation of the TMJ will result in fewer symptoms or improve functionality.

**Scoliosis**
Manipulative care has been utilized for the treatment of idiopathic scoliosis however evidence is lacking; the efficacy of manual therapy for correcting the scoliotic curve or progression of the curve has not been established in the peer-reviewed published scientific literature.

Four systematic reviews have reported on manual therapy for the treatment of idiopathic scoliosis, (Everett and Patel 2007); Romano and Negrini, 2008; Gleberzon, 2012; Posadzki, et.al., 2013). Two of the reviews have been appraised as “high quality” (Gleberzon, et.al, 2012; Posadzki, et.al., 2013). All of the reviews arrived at similar conclusion; there is a lack of evidence which does not permit conclusions on the efficacy of manual therapy including spinal manipulation for the treatment of adolescent and adult idiopathic scoliosis.

Additional clinical evidence indentified consisted of case reports.

**Extremity Disorders**
A comprehensive review by Bronfort et al. (2010) evaluated the effectiveness of manual therapies including manipulation for a broad range of extremity disorders. The following had positive results: shoulder girdle pain and dysfunction, adhesive capsulitis, hip osteoarthritis, knee osteoarthritis, patello-femoral syndrome, and plantar fascitis (when combined with exercise). This determination was made based on the results of the most recent and most updated (spans the last five to ten years) systematic reviews of RCTs, widely accepted evidence-based clinical guidelines and/or technology assessment reports, and all RCTs not yet included in the first three categories. The conclusions regarding effectiveness were based on comparisons with placebo controls (efficacy) or commonly used treatments which may or may not have been shown to be effective (relative effectiveness), as well as comparison to no treatment.

In a systematic review of 6 randomized controlled trials identified to have a low risk of bias, Sutton et al. (2016) evaluated the effectiveness of multimodal care for the management of musculoskeletal disorders of the elbow, forearm, wrist and hand on self-rated recovery, functional recovery or clinical
outcomes in adults or children. Therapeutic modalities included a combination of: manual therapy (manipulation, mobilization, traction), soft-tissue therapies (e.g., massage, muscle energy technique), acupuncture, education, exercise, passive physical modalities (e.g., heat application, cryotherapy, ultrasound, splints, braces), prescribed medication (e.g., acetaminophen, non-steroidal anti-inflammatory drugs), psychological interventions (e.g., relaxation, biofeedback). Based on the outcome of their review, the authors reported that there may be a role for multimodal care in the management of patients with persistent lateral epicondylitis, specifically including manual therapy. The evidence did not support the use of multimodal care for the management of carpal tunnel syndrome. This systematic review highlights the need for further high quality studies to determine the effectiveness of multimodal care for musculoskeletal disorders of the elbow, forearm, wrist and hand.

**Shoulder**

Horst et al. (2017) conducted a randomized controlled study of 66 patients diagnosed with a limited range of motion and pain in the shoulder region (frozen shoulder) to compare the short- and long-term effects of a structural-oriented (manual therapy) with an activity-oriented program. Both groups received 10 days of therapy, 30 minutes each day. The activity-oriented group (n = 33, mean = 44 years, SD = 16 years) included 20 males (61%) and the structural-oriented group (n = 33, mean = 47 years, SD = 17 years) included 21 males (64%). The authors reported that the activity-oriented group revealed significantly greater improvements in the performance of daily life activities and functional and structural tests compared with the group treated with conventional therapy after 10 days of therapy and at the three-month follow-up (p < 0.05).

In an updated Cochrane review on the effectiveness of manual therapy and exercise for rotator cuff disease compared to placebo, no intervention, or other therapies, Page et al. (2016) did not identify any clinically important differences between groups in any outcome. The authors recommend that novel combinations of manual therapy and exercise be compared with a realistic placebo in future trials, and that further trials of manual therapy alone or exercise alone for rotator cuff disease should be based upon a strong rationale and consideration of whether or not they would alter the conclusions of their review.

Ho et al. (2009) conducted a systematic review of 14 randomized controlled trials to evaluate the effectiveness of manual therapy (MT) techniques (including massage, joint mobilization and manipulation) for shoulder disorders. Results were analyzed within diagnostic subgroups (adhesive capsulitis (AC), shoulder impingement syndrome [SIS], non-specific shoulder pain/dysfunction) and a qualitative analysis using levels of evidence to define treatment effectiveness was applied. The authors concluded there was no clear evidence to suggest additional benefits of manual therapy to other interventions for shoulder impingement syndrome. The findings of the higher quality studies, however, favored manual therapy for pain reduction over exercise-alone and conventional physiotherapy-alone. Ranges of motion (ROM) outcomes were equivalent between groups receiving manual therapy and conventional physiotherapy. Studies that measured shoulder function favored the addition of manual therapy to exercises and were more effective than other physiotherapy procedures employed. In contrast, manual therapy was no more effective than other interventions in improving pain, range of motion, and function for the treatment of adhesive capsulitis. For non-specific shoulder pain/dysfunction, manual therapy was effective in reducing pain and short-term active range of motion, when compared to control groups and sham treatment. Perceived recovery favored manual therapy at both short-term and long-term follow-up.
Green et al. (2003) conducted a Cochrane review of 26 trials evaluating physiotherapy interventions for shoulder pain. Of the 26 trials included in the review, only 3 studies evaluated manual therapy and mobilization with and without exercise. The authors noted that combining mobilization with exercise resulted in additional benefit when compared to exercise alone for rotator cuff disease; however the same is not true for adhesive capsulitis.

Bergman et al. (2004) conducted a randomized, controlled trial of 150 patients with shoulder symptoms and dysfunction of the shoulder girdle. Patients were evenly allocated to receive manipulative therapy plus usual medical care (n=79) or usual medical care alone (n=71). Patients were prescribed oral analgesics or nonsteroidal anti-inflammatory drugs if necessary and if this was not effective, patients could receive up to 3 corticosteroid injections. Patients were followed for 52 weeks. Outcomes were measured by patient-perceived recovery, severity of the main complaint, shoulder pain, shoulder disability, and general health. During treatment (6 weeks), no significant differences were found between study groups. After completion of treatment (12 weeks), 43% of the intervention group and 21% of the control group reported full recovery. After 52 weeks, approximately the same difference in recovery rate (17 percentage points) was seen between groups. The authors concluded that manipulative therapy for the shoulder girdle in addition to usual medical care accelerates recovery of shoulder symptoms.

A prospective study by Mintken et al. (2010) utilized 5 prognostic factors associated with shoulder pain in 80 individuals to determine if cervical and thoracic spine manipulation would improve pain and disability. Participants underwent a standardized examination and then a series of thrust and non-thrust manipulations directed toward the cervicothoracic spine. Outcomes were measured using a 15-point Global Rating of Change (GROC) scale as well as outcomes from the prognostic variables. The GROC scale ranges from -7 (“a very great deal worse”) to 0 (“about the same”) to +7 (“a very great deal better”). Patients who rated their score as +4 or better were categorized as having a successful outcome. A total of 49 patients (61%) experienced a successful outcome. Mean Shoulder Pain and Disability Index (SPADI) scores decreased by more than 50% (from 38.1 to 18.4) in the successful group compared to 18% (from 37.9 to 30.4) in the non-successful group. Numeric pain rating scale (NPRS) scores also showed greater improvements in the successful group compared to the non-successful group. The participants’ ability to flex the shoulder without pain improved significantly in both groups. The authors found that if 3 of the 5 variables were present, the chance of achieving a successful outcome improved from 61% to 89%. The study is limited by small sample size, lack of a control group and no long term followup.

Elbow, Wrist or Hand
Burnham et al. (2015) conducted a single-blinded quasi-controlled trial to evaluate the effectiveness of OMT in the management of carpal tunnel syndrome. Patients underwent weekly OMT sessions for 6 consecutive weeks. The main outcome measures were the Boston Carpal Tunnel Syndrome Questionnaire (BCTQ), a sensory symptom diagram (SSD), patient estimate of overall change, electrophysiologic testing of the median nerve (trans-carpal tunnel motor and sensory nerve conduction velocity and amplitude ratio), and carpal tunnel ultrasound imaging of the cross-sectional area of the median nerve and transverse carpal ligament length and bowing. The authors reported that OMT resulted in patient-perceived improvement in symptoms and function associated with CTS. However, median nerve function and morphology at the carpal tunnel did not change, possibly indicating a
different mechanism by which OMT acted, such as central nervous system processes. Limitations of this study include unknown patient population and short follow-up period.

Two systematic reviews encompassing a range of physiotherapies for lateral epicondylitis concluded the evidence is insufficient for most physiotherapy interventions including manipulation or mobilization. (Bisset et al., 2005; Smidt et al., 2003)

Two systematic reviews that included an assessment of extraspinal manipulation or mobilization for carpal tunnel syndrome reached disparate conclusions. A Cochrane review by O’Connor et al. (2003) of non-surgical treatment (other than steroid injection) for carpal tunnel syndrome concluded, “Current evidence shows significant short-term benefit from oral steroids, splinting, ultrasound, yoga and carpal bone mobilization... More trials are needed to compare treatments and ascertain the duration of benefit.” Goodyear-Smith and Arroll (2004) also authored a systematic review of nonsurgical treatment options for carpal tunnel syndrome. This review found, “The evidence does not support the use of nonsteroidal anti-inflammatory drugs, diuretics, pyridoxine (vitamin B6), chiropractic [manipulative] treatment, or magnet treatment.”

In a comparative study by Struijs et al. (2003), 31 patients with lateral epicondylitis were randomly assigned to receive either manipulation of the wrist (n=15) or ultrasound, friction massage, and muscle stretching and strengthening exercises (n=16). Follow-up was at 3 and 6 weeks with 3 patients electing to drop out of the study. After 3 and 6 weeks of intervention, no differences in mean improvement in range of motion was found within or between the groups. The authors were unable to definitively conclude the effectiveness of manipulation and recommend further research with randomization, and longer-term follow-up to further evaluate the use of manipulation for lateral epicondylitis.

**Hip osteoarthritis**

A randomized clinical trial by Hoeksma et al. (2004) evaluated 109 patients with osteoarthritis of the hip to compare the effectiveness of a manual therapy (n=56) with exercise therapy (n=53) with a mean age of 72 years. The manual therapy group received therapy including manipulations and vigorous stretching while the control group received standard exercise therapy, which may have included stretching but did not include manipulation. The treatment period was 5 weeks (9 sessions). Outcomes were measured by general perceived improvement after treatment, level of pain, hip function, walking speed, range of motion, and quality of life. No major differences were found on baseline characteristics between groups. Success rates (primary outcome) after 5 weeks were 81% in the manual therapy group and 50% in the exercise group. Furthermore, patients in the manual therapy group had significantly better outcomes on pain, stiffness, hip function, and range of motion with results maintained after 29 weeks. The authors concluded that manual therapy is superior to exercise therapy for patients with OA of the hip.

Systematic reviews and meta-analyses were conducted by Sampath et al. (2016) and Beumer et al. (2016) to explore the effects of exercise and manual therapy on pain associated with hip osteoarthritis (OA). Best available evidence in both studies indicated that exercise therapy is more effective than minimal control in managing pain associated with hip OA in the short term. Low quality evidence in the Sampath et al. study showed a benefit of manual therapy in short-term pain control. Larger high-quality RCTs are needed to establish the effectiveness of exercise and manual therapies in the medium and long term in the treatment of hip OA.
In their systematic review and meta-analysis of manual therapy in the treatment of hip OA, Wang et al. (2015) reported that limitations of their systematic review included the paucity of literature and inevitable heterogeneity between included studies and due to this, they were unable to find any evidence that manual therapy benefits the patients at short-, intermediate- or long-term follow-up.

**Knee osteoarthritis**
Licciardone et al. (2004) conducted a randomized controlled trial of 30 patients who recently underwent surgery for knee osteoarthritis to evaluate the efficacy of osteopathic manipulative treatment (OMT) in the hospital setting. Patients were randomly assigned to receive either OMT or sham treatment. Patients receiving OMT for knee osteoarthritis had longer length of stays, decrease efficiency in rehabilitation and vitality. The authors concluded that osteopathic manipulative treatment does not appear to be efficacious in this hospital rehabilitation population.

In a systematic review and meta-analysis of manual therapy for the treatment of OA of the knee, Salamh et al. (2016) reported that their findings support the use of manual therapy versus a number of different comparators for improvement in self-reported knee function. As lesser support is present for pain reduction, the authors were not able to make an endorsement of functional performance at the time. The conclusions were based on 12 studies; 4 of which were felt to have a low risk for bias and high treatment fidelity.

**Ankle and Foot**
Plaza-Manzano et al. (2016) conducted a randomized single-blind controlled clinical trial to analyze the effects of proprioceptive strengthening exercises versus the same exercises and manual therapy in the management of recurrent ankle sprains (n=56). The control group performed 4 weeks of proprioceptive strengthening exercises; the experimental group performed 4 weeks of the same exercises combined with manual therapy (mobilizations to influence joint and nerve structures). Pain, self-reported functional ankle instability, pressure pain threshold (PPT), ankle muscle strength, and active range of motion (ROM) were evaluated in the ankle joint before, just after and one month after the interventions. The authors concluded that the protocol involving proprioceptive and strengthening exercises and manual therapy resulted in greater improvements in pain, self-reported functional joint stability, strength and ROM compared to exercises alone. Larger studies with longer follow-up periods are needed.

Cleland et al. (2009) conducted a multicenter randomized clinical trial of 60 patients with plantar heel pain to compare the effectiveness of electrophysical agents and exercise (EPAX) which included iontophoresis with dexamethasone and stretching of the gastrocnemius muscle and/or plantar fascia or a manual physical therapy and exercise (MTEX) which included aggressive soft tissue mobilization directed at the triceps surae and the insertion of the plantar fascia at the medial calcaneal tubercle. Patients were equally split between the control and treatment groups and followed for 6 months. Outcomes were measured utilizing a number of patient self-report questionnaires, including the Lower Extremity Functional Scale (LEFS), the Foot and Ankle Ability Measure (FAAM), and the Numeric Pain Rating Scale (NPRS). The primary aim (effects of treatment on pain and disability) was examined with a mixed-model analysis of variance (ANOVA). Both groups demonstrated a significant improvement over time; however, the patients receiving in the MTEX group experienced greater clinical benefits in terms of function and pain than the patients in the EPAX group.
A randomized trial by du Plessis et al. (2011) compared manual and manipulative therapy (MMT) with standard care of a night splint(s) for symptomatic mild to moderate hallux abducto valgus (HAV). Thirty patients were equally assigned to each group. The control group used a night splint(s) while the experimental group (MMT) received 4 MMT 4 treatments over a 2-week period. Outcomes were measured with visual analogue scale, foot function index and hallux dorsiflexion. Outcome measure scores in the control group (night splint) regressed between the 1-week followup and 1-month follow-up when patients did not use the night splint, while the scores in the experimental group (MMT) were sustained up to the 1-month follow-up. The authors concluded that a structured protocol of manual and manipulative therapy is equivalent to standard care of a night splint(s) for symptomatic mild to moderate HAV in the short term.

A pilot study by Pellow and Brantingham (2001) evaluated the use of manipulation in 30 patients with ankle sprain. Patients were equally divided to receive either an adjustment or ultrasound treatment over 4 weeks. While both groups showed improvement, the authors found that the adjustment group had greater reduction in pain, increased ankle range of motion, and ankle function.

Craniosacral therapy (CST)
Haller et al. (2016) conducted a randomized controlled clinical trial with a parallel-group design and 3 months of follow-up observation to investigate the efficacy of CST in chronic nonspecific neck pain in comparison with a manual sham control intervention. Patients (n=54) were randomized into either the CST group or an active attention-control group receiving light-touch sham treatment. Outcome measures were collected at week 8 after randomization (after intervention) and week 20 after randomization (3-month follow-up). The primary outcome was the average pain intensity during the last 7 days, recorded on a 100-mm VAS at week 8. Secondary outcomes were pain on movement, pressure pain sensitivity, neck pain-related disability, health-related quality of life, well-being, anxiety and depression, stress perception, pain acceptance, body awareness, patients’ global impression of improvement, and safety. Based on the outcomes, the authors concluded that CST was both specifically effective and safe in reducing neck pain intensity and may improve functional disability and the quality of life up to 3 months after intervention. Limitations to this study include concurrent analgesic use, small sample size, short follow-up period, and primarily subjective outcome measures.

A systematic review to evaluate the benefits of CST identified the scarcity of CST research in patients with different clinical pathologies (Jäkel and von Hauenschild, 2012). In the authors’ opinion, CST assessment is feasible in randomized controlled trials and has the potential of providing valuable outcomes to further support clinical decision making. However, due to the current moderate methodological quality of the included studies, further research is needed. The conclusion was based on 7 studies which met the inclusion criteria, of which three studies were RCTs and four were of observational study design. Positive clinical outcomes were reported for pain reduction and improvement in general well-being of patients.

In a preliminary report on the utility of CST techniques in the treatment of patients with lumbosacral spine overload Białoszewski et al., (2014) compared its effectiveness to that of trigger point therapy, another type of therapeutic approach. The authors concluded that both CST and trigger point therapy may be clinically effective in the treatment of patients with non-specific lumbosacral spine pain, and that the present findings represent a basis for conducting further and prospective studies of larger and randomized samples.
Manipulative Therapy with Non-Standard Techniques

Published peer-reviewed literature was not identified for non-standard manipulative therapy techniques such as applied kinesiology, NUCCA, and neural organizational technique (NOT).

The role of manipulation using non-standard techniques has not been established in scientific literature. A beneficial impact on health outcomes, e.g., improved physical function, durable pain relief, has not been established.

Professional Societies

American Osteopathic Association (AOA)

In a systematic review on the use of osteopathic manipulative treatment (OMT) in patients with low back pain (LBP), the AOA’s updated clinical guideline (2016) concludes that this therapy significantly reduces pain and improves functional status in patients, including pregnant and postpartum women, with nonspecific acute and chronic LBP. The AOA recommends that larger randomized controlled trials with robust comparison groups be conducted to further validate the effects of OMT on LBP. In addition, more research is needed to understand the mechanics of OMT and its short- and long-term effects, as well as the cost-effectiveness of such treatment.

American College of Physicians and the American Pain Society (ACP/APS)

Clinical guidelines published jointly by ACP and APS for the diagnosis and treatment of low back pain recommend spinal manipulation for patients who do not improve with self-care options along with a number of other nonpharmacological therapies, (Chou et al., 2007).

APPLICABLE CODES

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies and Coverage Determination Guidelines may apply.
